Theodorus Activator PC/Windows

There's nothing quite like launching SQLite's simple command line app and then realizing that you can run arbitrary SQL or Python scripts, and can change and explore databases. But you can't do that from the standard .NET DataSet designer, you'd have to write your own UIs and so you might as well do that in the C# language itself, right? So Theodorus is a simple, SQLite GUI with the goal of making SQLite experience a little closer to the powerful database explorer that databases programmers have long associated with SQLite.

Theodorus Features:

- * SQLite database access through readable .NET objects
- * Syntax highlighting and code completion, full support for SQLite 3.x and Python

What's New In?

SQLite is an open source SQL database engine, designed as a serverless, zero-configuration, transactional SQL database engine. It is currently used by gEdit, the GTK+ text editor, Sni-qt, the Qt-based menu editor, gVim, the Vi-inspired text editor, and several other applications. SQLite has been implemented completely in native code with no external dependencies. SQLite has a small command language with a simple wire format that makes it ideal for embedding in other applications, and the ability to create your own custom SQL functions. The database engine used by SQLite is a complete, full-featured, embedded, and SQL-92 compliant relational database management system. It supports UNDO and transaction control and implements INSERT, UPDATE, and DELETE. This project includes Theodorus, an interactive graphical SQL browser and editor, with tools for query analysis, import and export.

I used to handle XMLHttpRequest response errors on the server side using try/catch blocks. But in a recent project I had to look into the client-side response handling code and did not like the way it was done. That's why I developed a simple solution for the error handling of XMLHttpRequest (XHR). This solution also creates the concept of two global object files that are used to handle these types of errors. First, you should implement the XMLHttpRequest error event. That event is triggered if the request fails due to some error. The event handler receives an object with two properties called code and detail. The code property contains the error number and the detail property contains a string that indicates the error message. If you want to add properties for the error event handler, you can add them like shown below. The event handler can be written in a specific type called an extendable class. In the above example,
